

LITHIUM ION BATTERY CHARGER USING C8051F300

Relevant Devices

This application note applies to the following devices:
C8051F300

Introduction

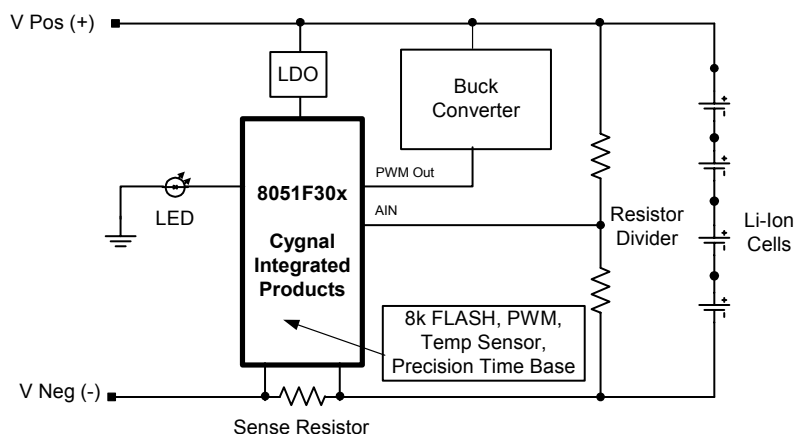

Driven by the need for untethered mobility and ease of use, many systems rely on rechargeable batteries as their primary power source. The battery charging circuitry for these systems is typically implemented using a fixed-function IC to control the charging current/voltage profile.

The C8051F30x family provides a flexible alternative to fixed-function battery chargers. This application note discusses how to use the C8051F30x family in Li-Ion battery charger applications. The Li-Ion charging algorithms can be easily adapted to other battery chemistries, but an understanding of other battery chemistries is required to ensure proper charging for those chemistries.

Key Points

- On-chip high-speed, 8-bit ADC provides superior accuracy in monitoring charge voltage (critical to prevent overcharging in Li-Ion applications), maximizing charge effectiveness and battery life.
- On-chip PWM provides means to implement buck converter with a very small external inductor.
- On-chip Temp sensor provides an accurate and stable drive voltage for determining battery temperature. An external RTD (resistive temperature device) can also be used via the flexible analog input AMUX.
- A single C8051F30x platform provides full product range for multi-chemistry chargers, expediting time to market and reducing inventory.

Figure 1. Lithium Ion Battery Charge Block Diagram.

Charging Basics

Batteries are exhaustively characterized to determine safe yet time-efficient charging profiles. The optimum charging method for a battery is dependent on the battery's chemistry (Li-Ion, NiMH, NiCd, SLA, etc.). However, most charging strategies implement a 3-phase scheme:

1. Low-current conditioning phase
2. Constant-current phase
3. Constant-voltage phase/charge termination

All batteries are charged by transferring electrical energy into them (refer to the references at the end of this note for a battery primer). The maximum charge current for a battery is dependent on the battery's rated capacity (C). For example, a battery with a cell capacity of 1000mAh is referred to as being charged at 1C (1 times the battery capacity) if the charge current is 1000mA. A battery can be charged at 1/50C (20 mA) or lower if desired. However, this is a common trickle-charge rate and is not practical in fast charge schemes where short charge-time is desired.

Most modern chargers utilize both trickle-charge and rated charge (also referred to as bulk charge) while charging a battery. The trickle-charge current is usually used in the initial phases of charging to minimize early self heating which can lead to premature charge termination. The bulk charge is usually used in the middle phase where the most of the battery's energy is restored.

During the final phase of battery charge, which generally takes the majority of the charge time, either the current or voltage or a combination of both are monitored to determine when charging is complete. Again, the termination scheme depends on the battery's chemistry. For instance, most Lithium Ion battery chargers hold the battery voltage constant, and monitor for minimum current. NiCd

batteries use a rate of change in voltage or temperature to determine when to terminate.

Note that while charging a battery, *most* of the electrical energy is stored in a chemical process, but not *all* as no system is 100 percent efficient. Some of the electrical energy is converted to thermal energy, heating up the battery. This is fine until the battery reaches full charge at which time *all* the electrical energy is converted to thermal energy. In this case, if charging isn't terminated, the battery can be damaged or destroyed. Fast chargers (chargers that charge batteries fully in less than a couple hours) compound this issue, as these chargers use a high charge current to minimize charge time. As one can see, monitoring a battery's temperature is critical (especially for Li-Ion as they explode if over-charged). Therefore, the temperature is monitored during all phases. Charge is terminated immediately if the temperature rises out of range.

Li-Ion Battery Charger - Hardware

Currently, Li-Ion batteries are the battery chemistry of choice for most applications due to their high energy/space and energy/weight characteristics when compared to other chemistries. Most modern Li-Ion chargers use the tapered charge termination, minimum current (see Figure 2), method to ensure the battery is fully charged as does the example code provided at the end of this note.

Buck Converter

The most economical way to create a tapered termination charger is to use a buck converter. A buck converter is a switching regulator that uses an inductor and/or a transformer (if isolation is desired), as an energy storage element to transfer energy from the input to the output in discrete packets (for our example we use an inductor; the capacitor in Figure 3 is used for ripple reduction). Feedback circuitry regulates the energy transfer via the transistor, also referred to as the pass switch, to maintain a constant voltage or constant current

Figure 2. Lithium Ion Charge Profile.

within the load limits of the circuit. See Figure 3 for details.

Tapered Charger Using the F30x

Figure 3 illustrates an example buck converter using the 'F30x. The pass switch is controlled via the on-chip 8-bit PWM (Pulse Width Modulator) output of the PCA. When the switch is on, current will flow like in Figure 3A. The capacitor is charged from the input through the inductor. The inductor is also charged. When the switch is opened (Figure 3B), the inductor will try to maintain its current flow by inducing a voltage as the current through an inductor can't change instantaneously. The current then flows through the diode and the inductor charges the capacitor. Then the cycle repeats itself. On a larger scale, if the duty cycle is decreased (shorter "on" time), the average

voltage decreases and vice versa. Therefore, controlling the duty cycles allows one to regulate the voltage or the current to within desired limits.

Selecting the Buck Converter Inductor

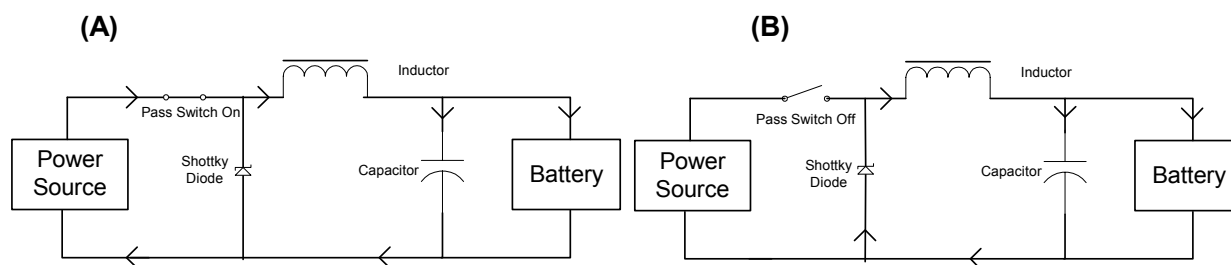

To size the inductor in the buck converter, one first assumes a 50 percent duty cycle, as this is where the converter operates most efficiently.

Duty cycle is given by Equation 1, where T is the period of the PWM (in our example $T = 10.5\mu\text{s}$).

$$\text{DutyCycle} = \frac{t_{\text{on}}}{T}$$

Equation 1. Duty Cycle.

Figure 3. Buck Converter.

With this established, select a PWM switching frequency. As [Equation 2](#)

$$L = \frac{(V_i - V_{sat} - V_o) t_{on}}{2I_{Omax}}$$

Equation 2. Inductor Size.

shows, the larger the PWM switching frequency, the smaller (and more cost effective) the inductor. Our example code configures the ‘F30x’s 8-bit hardware PWM to use the internal master clock of 24.5MHz divided by 256 to generate a 95.7kHz switch rate.

Now we can calculate the inductor’s size. Assuming V_i , the charging voltage, is 15V, V_{sat} , the saturation voltage, is 0.5V, the desired output voltage, V_o , is 4.2V, and I_{Omax} , the maximum output current, is 1500 mA, the inductor should be at least 18 μ H.

Note that the capacitor in this circuit is simply a ripple reducer. The larger it is the better as ripple is inversely proportional to the size of the cap. For more details on buck converters, refer to the references listed at the end of this note.

Li-Ion Battery Charger - Software

The software example that follows demonstrates a Li-Ion battery charger using the C8051F300. The F300 is designed for high-level languages like “C” and includes an 8-bit 8051 based micro-controller, an 8-bit 500 kbps ADC, 8k FLASH, an 8-bit and 16-bit PWM, and a 2% accurate oscillator all on-chip. The algorithms discussed are written entirely in “C” making them easily portable. Refer to the F300’s datasheet for a full description of the device.

Calibration

To ensure accurate voltage and current measurements, the algorithms use a two-point system calibration scheme. In this scheme, the user is expected to apply two known voltages and two known currents, preferable, one point near ground and the other point near full-scale. The algorithm then takes these two points, calculates a slope and an offset for both the current and voltage channels, and stores the results in FLASH. All future conversions are scaled relative to these slope and offset calculations. Note that if an external amplifier is used for the current channel, it will need to be calibrated with a similar two-point calibration scheme to ensure maximum accuracy.

Temperature

To monitor the temperature, the algorithms use the on-chip temperature sensor. The sensor is left uncalibrated, but still provides a sufficiently accurate temperature measurement. For more accurate temperature measurement, one or two-point temperature calibration is required.

An external temperature sensor can be used if desired. The AMUX can to be reconfigured to accommodate this additional input voltage.

Current

The charge-current to the battery cells is monitored by taking a differential voltage reading across a small but accurate sense resistor. The current is amplified through the on-chip PGA, digitized by the on-chip 8-bit ADC, and scaled accordingly via the slope and offset calibration coefficients. An external gain stage may be necessary if more resolution is desired for the current measurement.

Voltage

The battery’s voltages are divided down and monitored via external resistors. Note that this example uses the supply voltage as the ADC voltage reference. Any monitored voltage above the reference voltage must be divided down for accurate moni-

toring. If a more accurate reference is required, an external voltage reference can be used. Adjustment to the divide resistors must be made accordingly.

Charging - Phase 1

In phase 1, (for description purposes, we assume the battery is initially discharged), the 'F30x regulates the battery's current to $I_{\text{LOWCURRENT}}$ (typically 1/50 C) until the battery's voltage reaches $V_{\text{MINVOLT BULK}}$. Note that the battery's charge current is current limited to $I_{\text{LOWCURRENT}}$ to ensure safe initial charge and to minimize battery self-heating. If at any time the temperature increases out of limit, charging is halted.

Charging - Phase 2

Once the battery reaches $V_{\text{MINVOLT BULK}}$ the charger enters phase 2, where the battery's algorithm controls the PWM pass switch to ensure the output voltage provides a constant charge-current I_{BULK} to the battery (rate or bulk current is usually 1C and is definable in the header file as is $I_{\text{LOWCURRENT}}$ and $V_{\text{MINVOLT BULK}}$).

Charging - Phase 3

After the battery reaches V_{Top} (typically 4.2 V in single cell charger), the charger algorithm enters phase 3, where the PWM feeds back and regulates the battery's voltage. In phase 3, the battery continues to charge until the battery's charge current reaches I_{MINIBULK} , after which, the battery is charged for an additional 30 minutes and then charge terminates. Phase 3 typically takes the majority of the charging time.

Note that in most practical applications, such as a portable PC, the batteries may be in any of the three phases when charging is activated. This doesn't really affect the charger as it simply monitor's the

battery's current condition and starts charging from that point.

Conclusion

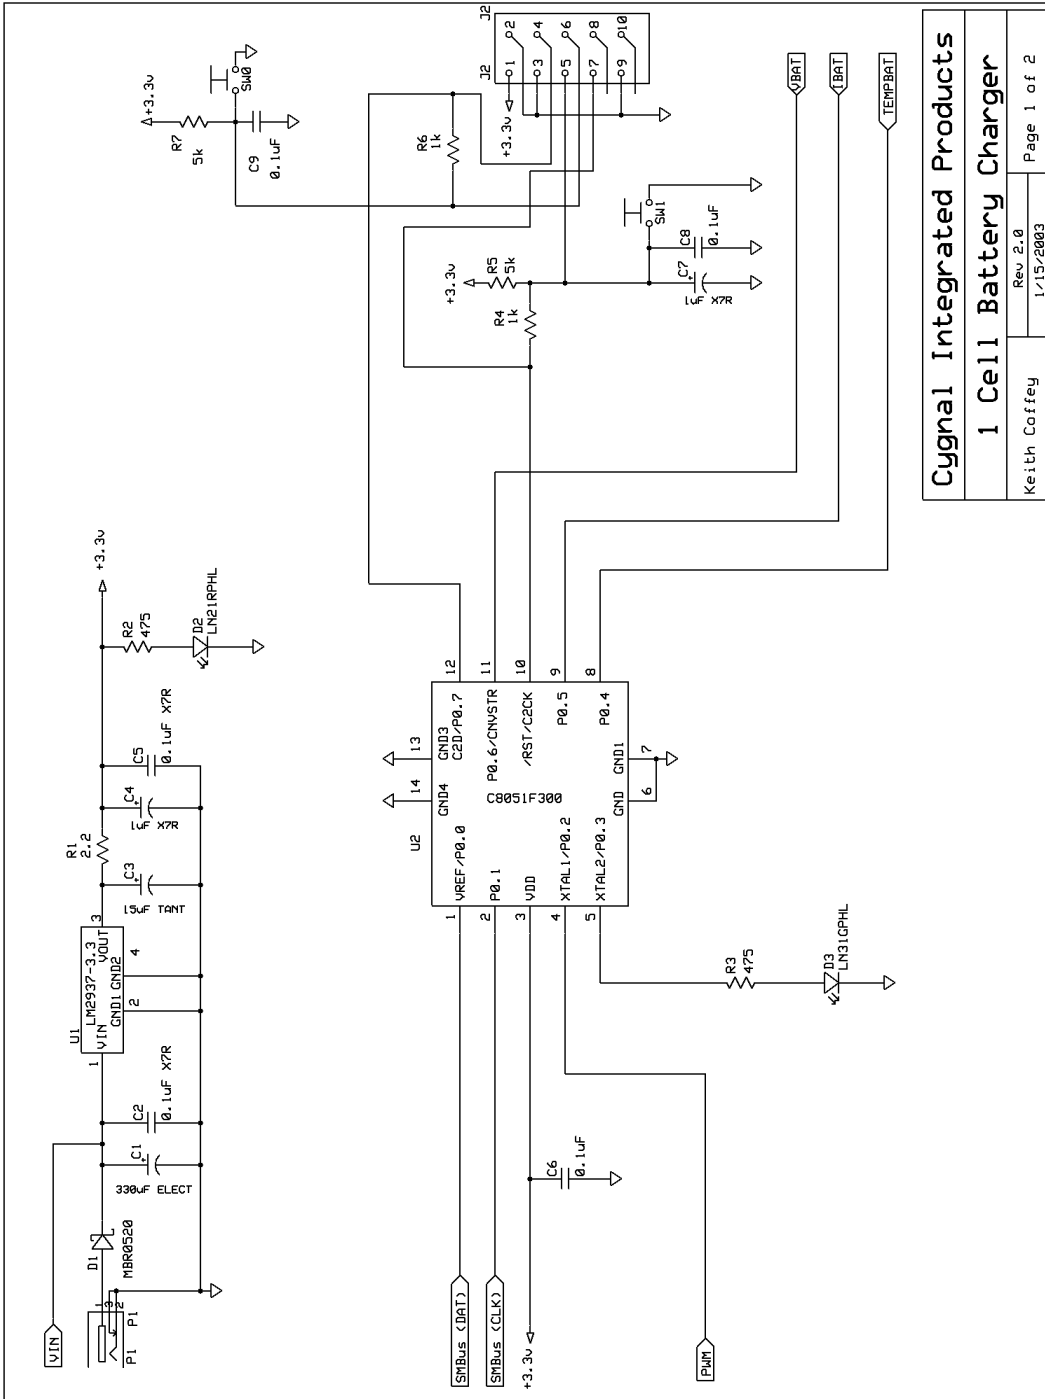

The C8051F300's high level of analog integration, small form-factor, integrated FLASH memory, and low power consumption makes it ideal for flexible next generation battery charging applications. This application note discussed how to use the C8051F30x family in Lithium Ion battery charger applications. Example code is provided as well.
